Lecture # 58
Computational Fluid Dynamics (Contd.,)

Welcome back to the last lecture of this module computational fluid dynamics and the last lecture we ended at a point where we saw the Reynolds shear stress equation. We discussed about the different terms in it you do not need to worry about the mathematical equation of those terms, but some common terms like Reynolds shear stress, those things are recommended that you remember them, but not the complex terms. So, the up in proceeding in the direction we are going to study the closure problem. So, the effect of the Reynolds shear stress $\rho \tau_{ij}$ as you can see on the slide now the effect of $\rho \tau_{ij}$ on the mean flow is like that of a stress term.

(Refer Slide Time: 01:14)

The slide has a yellow background with a blue header and footer. The title 'Closure Problem' is in red. The first bullet point states that the effect of $\rho \tau_{ij}$ on the mean flow is like that of a stress term. The second bullet point states that to obtain \bar{u}_i and \bar{p} from RANS equations, we need to model $\rho \tau_{ij}$ as a function of the average flow removing the fluctuations. A red arrow points from the second bullet point to the text 'Closure Problem' at the bottom. The footer contains two logos and a small video inset of a man.

Closure Problem

- The effect of $\rho \tau_{ij}$ on the mean flow is like that of a stress term.
- To obtain \bar{u}_i and \bar{p} from RANS equations, we need to model $\rho \tau_{ij}$ as a function of the average flow removing the fluctuations.

Closure Problem

So I am going to write here $\rho \tau_{ij}$ is actually Reynolds shear stress. So it is like shear stress to obtain u_i and pressure. So, u_i is the average flow velocities and pressure from RANS equation, we need to model this shear stress $\rho \tau_{ij}$ is a function of the average flow so if you look at the equations. So take you back to this.

(Refer Slide Time: 01:57)

- Averaging of the Navier- Stokes equation leads to:

$$\frac{\partial \bar{u}_i}{\partial t} + \frac{\partial \bar{u}_i \bar{u}_j}{\partial x_j} = -\frac{1}{\rho} \frac{\partial \bar{p}}{\partial x_i} + \frac{\partial}{\partial x_j} (-\tau_{ij} + 2\nu \bar{D}_{ij}) \quad (\text{Eq. 4})$$

- Using Eq. 2, the above equation can be expressed as:

$$\frac{D \bar{u}_i}{Dt} = -\frac{1}{\rho} \frac{\partial \bar{p}}{\partial x_i} + \frac{\partial}{\partial x_j} (-\tau_{ij} + 2\nu \bar{D}_{ij}) \quad (\text{Eq. 5})$$

fluctuations

Where we have written the Reynolds average here you see this particular equation this is average quantity that we need to find out this we need to find out these are the independent variables. D_i j we also know because this is the average value and it comprises of only this is the only term that has fluctuations and this increases our complexity. So, we need to be able to equate τ_{ij} to something that is known known or some unknown which we are actually calculating.

So, the best ways to put it in some form of an average value and to do that, that particular problem is called a closure problem. So, we will go back to the closure problem so as I said, to obtain u_i and pressure from Reynolds equation, we need to model this Reynolds's shear stress given by ρ into τ_{ij} as a function of average flow, this will remove the fluctuations and this process is called the closure problem.

(Refer Slide Time: 03:16)

$k - \varepsilon$ Model

- The model focuses on the mechanisms that effect the turbulent kinetic energy.
- The instantaneous kinetic energy $k(t)$ of a turbulent flow is the sum of the mean kinetic energy K and the turbulent kinetic energy k .

$$k(t) = \underbrace{K}_{\downarrow} + \underbrace{k}_{\downarrow} \rightarrow \frac{1}{2} (\overline{u'^2} + \overline{v'^2} + \overline{w'^2})$$

$$\frac{1}{2} (\overline{u^2} + \overline{v^2} + \overline{w^2})$$

There are elegant ways the first of the methods is called the k epsilon model. So, this in this technique the model focuses on the mechanism that effects the turbulent kinetic energy, k stands for kinetic energy. So, the instantaneous kinetic energy k as a function of time k t of a turbulent flow is the sum of the mean kinetic energy and the turbulent kinetic energy k. So, k of t can be written as capital K + small k.

So, this is small k and capital K is written is simply half u square + v squared + w squared actually u bar v bar and w bar and small k is written is half of u dash squared + v dash squared + w dash squared.

(Refer Slide Time: 04:23)

- The governing equations are:

$$\frac{\partial \overline{u_i}}{\partial x_i} = 0 \quad \text{Continuity Equation}$$

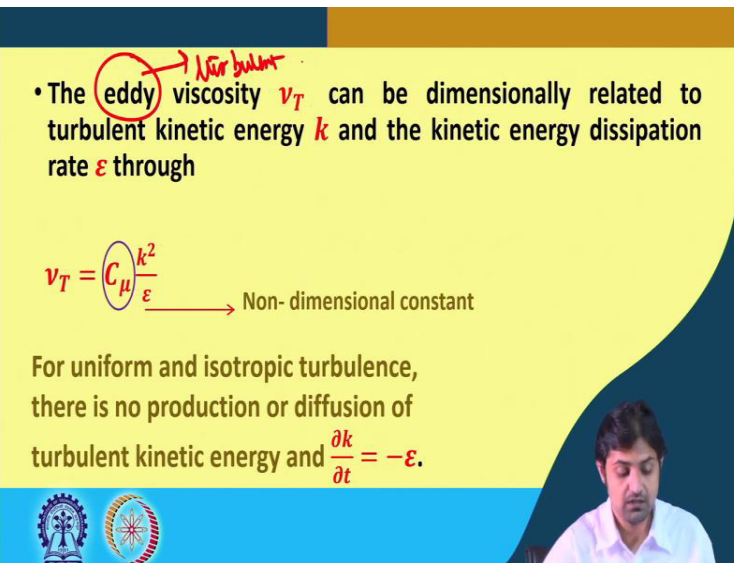

and

Momentum Equation

$$\frac{\partial \tau_{ij}}{\partial t} = -\frac{1}{\rho} \frac{\partial \overline{p}}{\partial x_i} + \frac{\partial}{\partial x_j} [2(\nu + \nu_T) \overline{D_{ij}}]$$

The governing equations for this are one we have continuity equation and the other is so, the way we write is So, $\frac{D}{Dt} \tau_{ij}$ that is what we are modeling is $-\frac{1}{\rho} \frac{\partial p}{\partial x_i} + \frac{\partial}{\partial x_j} (2\nu + \nu_t) \frac{\partial u_i}{\partial x_j}$. How does equations have been derived we are not going to discuss but these are the 2 equations that we use for momentum. See, it looks like a momentum equation itself so modeling of the Reynolds shear stress in as the momentum equation.

(Refer Slide Time: 05:05)

• The **eddy viscosity** ν_T can be dimensionally related to turbulent kinetic energy k and the kinetic energy dissipation rate ε through

$$\nu_T = C_\mu \frac{k^2}{\varepsilon}$$

Non-dimensional constant

For uniform and isotropic turbulence, there is no production or diffusion of turbulent kinetic energy and $\frac{\partial k}{\partial t} = -\varepsilon$.

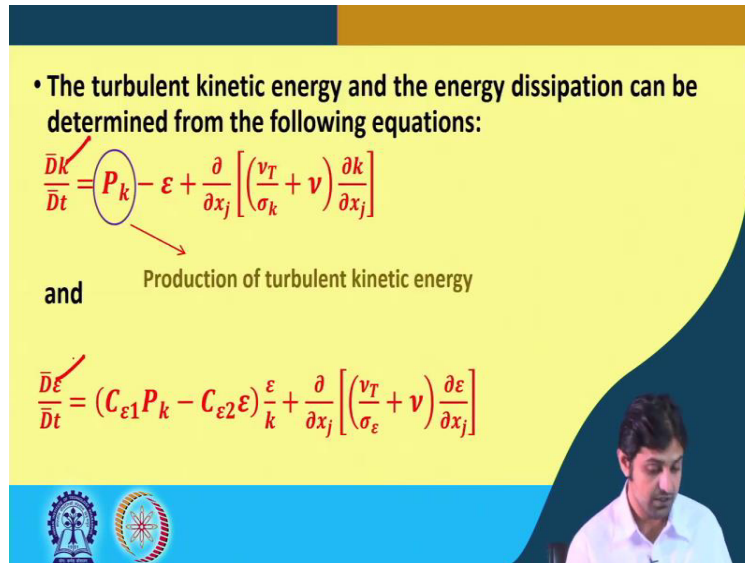

So, if you see there is a term called ν_T . So, this ν_t is the eddy viscosity. So, this actually is not should better be called as turbulent eddy viscosity, ν_T , it can be actually dimensionally related to kinetic energy k kinetic energy dissipation rate ε through ν_T is written as C_μ into k^2 by ε . So, ν_T we got also able to find on infinite terms of k and ε and we substitute this into this equation and C_μ is a non-dimensional constant. Which values we know from experiments for uniform and isotropic turbulence there is no production or diffusion of turbulent kinetic energy, therefore, $\frac{\partial k}{\partial t}$ will be equal to $-\varepsilon$.

(Refer Slide Time: 06:05)

• The turbulent kinetic energy and the energy dissipation can be determined from the following equations:

$$\frac{\overline{Dk}}{\overline{Dt}} = \underbrace{P_k}_{\text{Production of turbulent kinetic energy}} - \varepsilon + \frac{\partial}{\partial x_j} \left[\left(\frac{\nu_T}{\sigma_k} + \nu \right) \frac{\partial k}{\partial x_j} \right]$$

and

$$\frac{\overline{D\varepsilon}}{\overline{Dt}} = (C_{\varepsilon 1} P_k - C_{\varepsilon 2} \varepsilon) \frac{\varepsilon}{k} + \frac{\partial}{\partial x_j} \left[\left(\frac{\nu_T}{\sigma_\varepsilon} + \nu \right) \frac{\partial \varepsilon}{\partial x_j} \right]$$

The turbulent kinetic energy and the energy dissipation can be determined from the following equation. So, now, we said that this is the equation which we are going to use for determining τ_{ij} and that we can use in our average equation Reynolds average Navier stokes equation, we saw that there are some terms one is ν_t that we do not know again others are again like $\overline{\Delta p}$, $\overline{D_{ij}}$. Those are known means do quantity that are in terms of average quantities.

So ν_t is something that we yet do not know. And we write it ν_t in terms of C_μ into k square by epsilon. So, again, we have 2 things to again find out k and epsilon we still we do not know so, the next step is finding out this turbulent kinetic energy k and epsilon that that is how this equation gets in the model gets its name. And to be able to do that we have 2 another equation 1 is in terms of kinetic energy 1 is in terms of epsilon. And this is production of turbulent kinetic energy this term here. So, we use these 2 equation to solve for k and epsilon.

(Refer Slide Time: 07:36)

• The values of the constants in the above equations are:

- $C_\mu = 0.09$
- $\sigma_k = 1$
- $\sigma_\epsilon = 1.3$
- $C_{\epsilon 1} = 1.44$
- $C_{\epsilon 2} = 1.92$

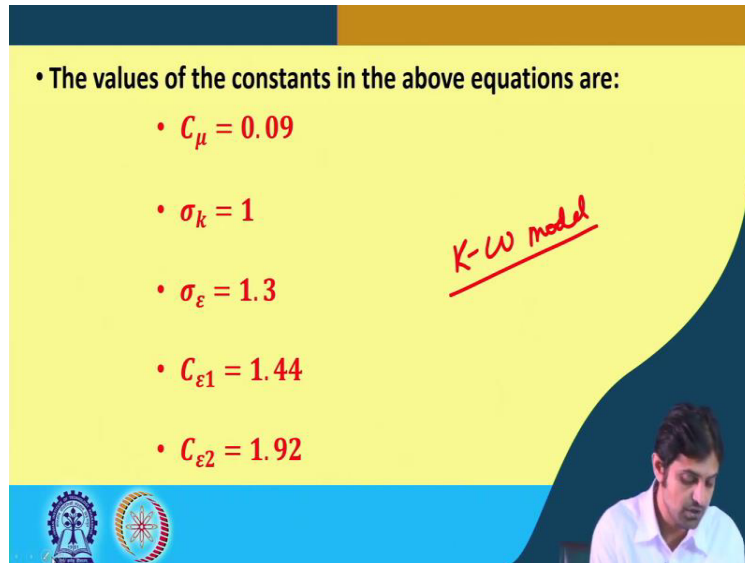

Handwritten notes:
 Solve for k & ϵ
 for $\frac{k^3}{\epsilon}$
 Reynolds shear stress equation
 ↓
 Reynolds averaged NS

And the values of the constant in above equation are $C_\mu = 0.09$, $\sigma_k = 1$ if you see, C_μ was there first, and then there is σ_k here then there is σ_ϵ here and also there are some terms there is σ_k there is the $C_{\epsilon 1}$ there is $C_{\epsilon 2}$. So, those things are already known these are the values that we use so, what we do is we solve the k and ϵ equations use those equations to find out the turbulent kinetic turbulent eddy viscosity ν_T put it into their an Reynolds shear stress equation.

And use it in the average equation of Reynolds Navier Stokes equation. So, this for just writing it down solve for k and ϵ then ν_T is related to k^2 by ϵ . ν_T , put this in Reynolds shear stress equation and use that in Reynolds average Navier stokes equations. It is a quite a complex way, but it gives good results.

(Refer Slide Time: 09:14)

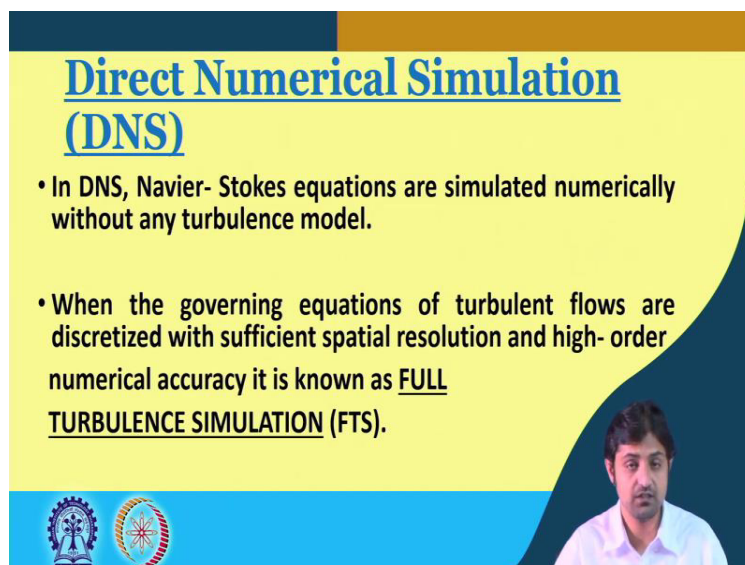

• The values of the constants in the above equations are:

- $C_\mu = 0.09$
- $\sigma_k = 1$
- $\sigma_\epsilon = 1.3$
- $C_{\epsilon 1} = 1.44$
- $C_{\epsilon 2} = 1.92$

K- ω model

Most of the turbulence model in the world follow k and epsilon, there is one other turbulence model for k omega. So, k is the same kinetic energy omega is somehow related to dissipation epsilon, but that is also the outside the scope, but it is better to remember the name. So, the other model is k omega model like epsilon, these are the two world's most widely used turbulence models, and some of each of them have their advantages and disadvantages.

(Refer Slide Time: 09:43)

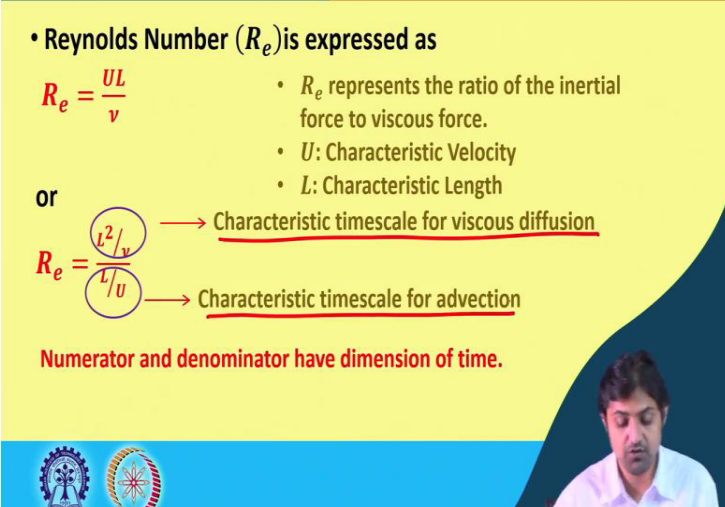

Direct Numerical Simulation (DNS)

- In DNS, Navier- Stokes equations are simulated numerically without any turbulence model.
- When the governing equations of turbulent flows are discretized with sufficient spatial resolution and high- order numerical accuracy it is known as FULL TURBULENCE SIMULATION (FTS).

So, another method apart from Reynolds average navier stokes equation for solving the turbulence, for solving the computational fluid dynamics navier stokes equation is called direct numerical simulation. So, in direct numerical simulation DNS navier stokes equation or simulated numerically without any turbulence model. So, they solve for the exact solution when

the governing equations of turbulent flows are discretized with sufficient spatial resolution and high order numerical accuracy, it is known as full turbulence simulation FTS.

(Refer Slide Time: 10:27)

• Reynolds Number (R_e) is expressed as

$$R_e = \frac{UL}{\nu}$$

- R_e represents the ratio of the inertial force to viscous force.
- U : Characteristic Velocity
- L : Characteristic Length

or

$$R_e = \frac{L^2/\nu}{L/U}$$

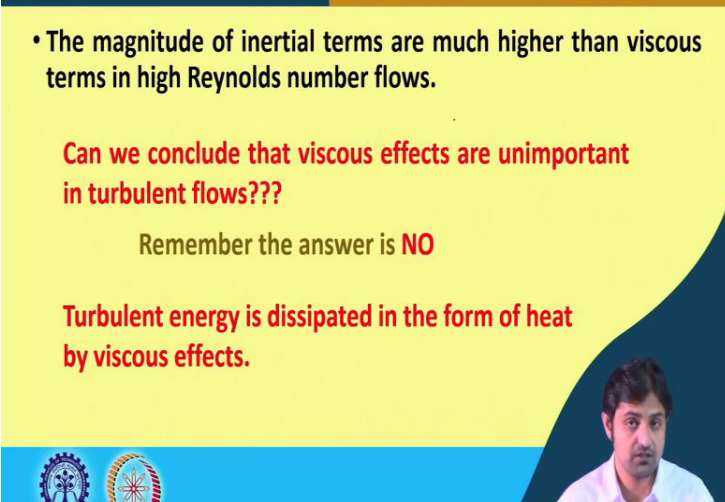

→ Characteristic timescale for viscous diffusion

→ Characteristic timescale for advection

Numerator and denominator have dimension of time.

So, in this modeling Reynolds number is expressed as UL/ν , where R_e represents the ratio of the inertial forces to viscous forces or Reynolds number, use the characteristic velocity L is the characteristic length or Reynolds number can also be written as L^2/ν divided by L/U . Numerator and denominators both have dimensions of time so, this L^2/ν is the characteristic timescale for viscous diffusion whereas L/U is the characteristics timescale for advection.

(Refer Slide Time: 11:13)

• The magnitude of inertial terms are much higher than viscous terms in high Reynolds number flows.

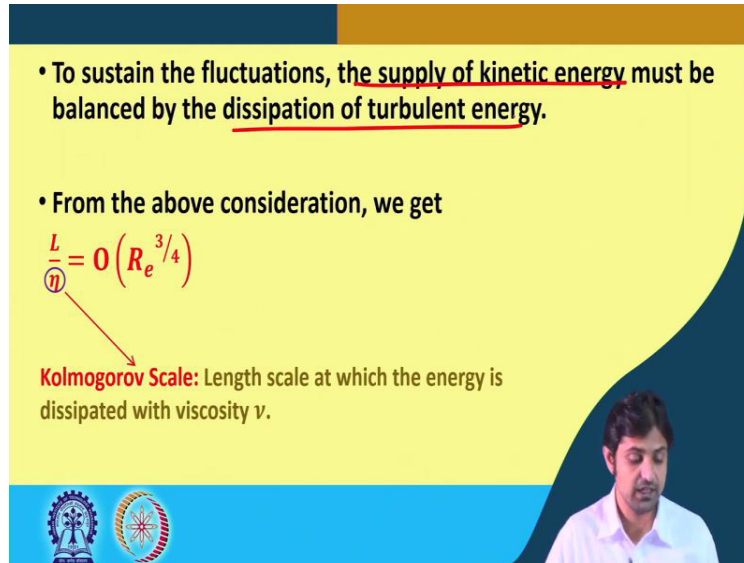

Can we conclude that viscous effects are unimportant in turbulent flows???

Remember the answer is **NO**

Turbulent energy is dissipated in the form of heat by viscous effects.

The magnitude of inertial terms are much higher than viscous term in high Reynolds number flows that is true, because it is the ratio of viscous diffusion because the ratio of the inertial forces to viscous forces. So, can we conclude that viscous effects are unimportant in turbulent flows no it is very important because turbulent energy is dissipated in form of heat by viscous effects? Therefore, the viscous effects are very important in high energy turbulent flows.

(Refer Slide Time: 11:56)

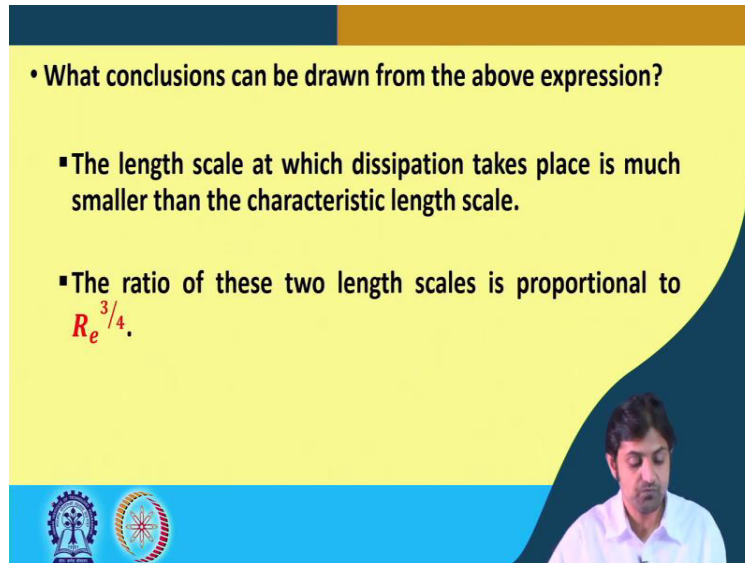

- To sustain the fluctuations, the supply of kinetic energy must be balanced by the dissipation of turbulent energy.
- From the above consideration, we get

$$\frac{L}{\eta} = O(R_e^{3/4})$$

Kolmogorov Scale: Length scale at which the energy is dissipated with viscosity ν .

To sustain the fluctuations the supply of kinetic energy must be balanced by these dissipation of turbulent energy this is important thing supply of kinetic energy must be balanced by the dissipation of turbulent energy. So, from the above consideration what we get is all definitely outside the scope the derivation of this that L by η is of the order of Reynolds number to the power 3 by 4 this this has been obtained and this η is a Kolmogorov length scale. So, it is the length scale at which the energy is dissipated with viscosity ν you should remember the order and everything but the derivation is not required.

(Refer Slide Time: 12:50)

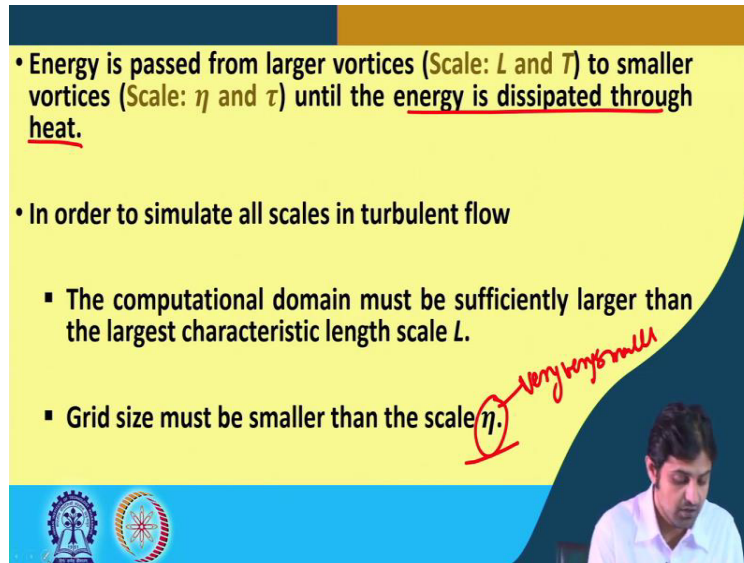

- What conclusions can be drawn from the above expression?
 - The length scale at which dissipation takes place is much smaller than the characteristic length scale.
 - The ratio of these two length scales is proportional to $Re^{3/4}$.

So, what can we convert conclusions can be drawn from the above expect expression this is important so, L by η so length of the flow divided by the Kolmogorov length scale at which energy is dissipated is the function of Reynolds number to the power 3 by 4. So, if this is the equation what are the conclusions from it? This means that the length scale at which the dissipation takes place is much smaller than the characteristic length scale. L by η is proportional to Re to the power so in turbulent flow and Reynolds number is very high.

So that means L by η is very high. This means numerator is much, much larger than the denominator. That is implying the length scale at which dissipation takes place is much η is much smaller than the characteristic length scale L . Valid conclusion from the equation. The ratio of these 2 length scale is proportional to Re to the power 3 by 4 as we have seen in the last slide.

(Refer Slide Time: 14:02)

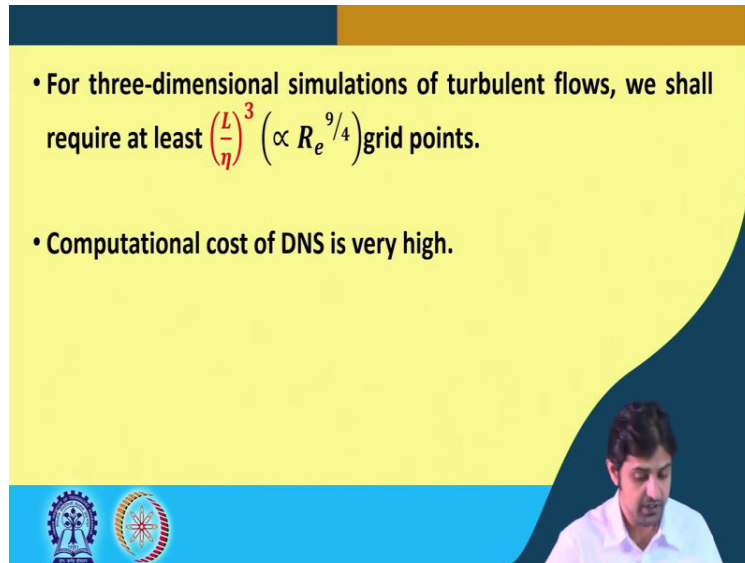

- Energy is passed from larger vortices (Scale: L and T) to smaller vortices (Scale: η and τ) until the energy is dissipated through heat.
- In order to simulate all scales in turbulent flow
 - The computational domain must be sufficiently larger than the largest characteristic length scale L .
 - Grid size must be smaller than the scale η . *very very small*

Second thing is the energy is passed from large vortices, that means, the flow is of the scale of length of L and T to smaller vortices that is, so, because see the dissipation happens at the Kolmogorov length scale. So, the eddies become transfer energy to each other they keep on losing the energy you know and until they become they come into range of this Kolmogorov length scale and at this point this energy is dissipated through the heat.

So, in order to simulate all the scales in turbulent flow So, now you see we have a length of scale from capital L to η it is Kolmogorov length scale which is of the order of several order of magnitude less than millimeters the computational domain must be sufficiently large than the characteristic length scale L . So, to see there will be what is this which will be of the length L as well so, the computational domain must be sufficiently large than the character length L .

But also it is important that the grid size must be smaller than this may then this then this it is very small of the order of 10^{-5} , 6 meters and length the scale of the typically of the order of let us say 1 or 2 meters or 10 to the power 1 meter, let us say so to be able to model all the type of energies energy in direct numerical simulation, the two things that are important is that the total domain means the study area should be larger than the length L which is of the order of meters several time 100 of meters but the grid size must be smaller than this Kolmogorov length scale which is very, small.

(Refer Slide Time: 16:15)

- For three-dimensional simulations of turbulent flows, we shall require at least $\left(\frac{L}{\eta}\right)^3 \left(\propto R_e^{9/4}\right)$ grid points.
- Computational cost of DNS is very high.

The implication of this is that for 3 dimensional simulation of turbulent flow we will require at least L by η to the power 3 that means, Reynolds number to the power 9 by 4 grid points let us say R_e is very, not very high Reynolds number let us see Reynolds number is 10 to the power 4. So, how many grids is needed? R_e that is 10 to the power 4 raise to the power 9 by 4. So, we need 10 to the power nine grids almost so much high more than billions.

You know around billion grids, which currently looking at the capacity of our computational facilities it is not possible. So, these things like R_e to the power 9 by 4, R_e to the power 3 by 4 those are the term which you must the values which you must remember for the computational cost of DNS is very high.

(Refer Slide Time: 17:32)
